Nitric oxide (NO) synthase in the vasculature (endothelial NO synthase [eNOS]) is constantly activated by the shear stress generated by circulating blood. The resulting NO, which activates soluble guanylate cyclase (sGC), maintains a vasodilator tone which is determinant in the regulation of blood flow and pressure.1 NO also interacts with the terminal enzyme of the electron transport chain, cytochrome c oxidase (CcO), in a manner that is competitive with oxygen (O2), leading to an increase in the $K_m$ of this enzyme for O2 and the consequent inhibition of respiration.2 A number of studies in vascular endothelial cells3 and in tissues4,5 have shown that this results in a decrease in consumption of O2 and in its redistribution away from mitochondria and toward other oxygen-dependent targets.6 Thus NO plays a role in the subcellular profile of O2 distribution. In this study, we have investigated this phenomenon by monitoring the dynamics of O2 consumption and its distribution both throughout the thickness of conductance vessels and in the microcirculation. Furthermore, we have shown that such modulation regulates O2 distribution to the surrounding tissues. We have demonstrated these effects by measuring O2 consumption in blood vessels in a hypoxic chamber and O2 distribution in the microcirculation using the fluorescent oxygen-probe Ru(phen)$_2$$^{2+}$. Removal of NO by physical or pharmacological means, or in eNOS$^{-/-}$ mice, abolishes this regulatory mechanism. Our results indicate that, in addition to its well-known effect on the regulation of vascular tone, endothelial NO plays a major role in facilitating the distribution of O2, an action which is crucial for the adaptation of tissues, including the vessel wall itself, to hypoxia. It is possible that changes in the distribution of O2 throughout the vessel wall may be implicated in the origin of vascular pathologies such as atherosclerosis. (Circ Res. 2009;104:1178-1183.)

Key Words: nitric oxide ■ endothelium ■ oxygen consumption

Materials and Methods

Tissue Preparation

Human umbilical cords were obtained from the Department of Gynaecology and Obstetrics of the Hospital Doctor Peset. Vascular rings, 5 mm in length, were extracted from the middle portion of the cords. Male Sprague–Dawley rats (200 to 250 g, Harlan Laboratories, Barcelona, Spain) or wild-type (WT) and eNOS knockout (eNOS$^{-/-}$) mice (WT, C57BL/6Jx129, 20 to 25 g, UCL, London, UK) were decapitated and their thoracic aortas and pulmonary and mesenteric arteries were removed, cleaned of adhering tissues, and cut into 5-mm (rat vessels) or 2-mm (mouse vessels) rings. When necessary, the endothelium was disrupted by gently rubbing the luminal surface. For the experiments with fluorescence microscopy, a portion of the rat or mouse mesenteric artery tree was isolated and cleaned of surrounding fat. All experiments were performed in Krebs solution (in 10$^{-3}$ mol/L NaCl 118, KCl 4.75, CaCl$_2$ 1.9, MgSO$_4$ 1.2, K$_2$HPO$_4$ 1.2, NaHCO$_3$ 25, and glucose 10.1). All protocols complied with the European Community guidelines for the use of experimental animals and were approved by the Ethics Committee of the University of Valencia.

Contractility Studies

These experiments were performed with rat vascular rings suspended in a 5-ml organ bath (37°C) gassed with 12% O$_2$, 5% CO$_2$, and 83% N$_2$, which produced an O$_2$ concentration of $\approx$130×10$^{-6}$ mol/L, similar to that present in the aortic blood,2 and monitored with a dissolved O$_2$ meter (ISO$_2$; World Precision Instruments, Stevenage, Herts, UK). Tension was measured isometrically with Grass FTO3...
force-displacement transducers and recorded (Power Laboratory). An initial load of 2 g (aorta and human umbilical artery) or 1 g (pulmonary and mesenteric arteries) was applied to each preparation and maintained throughout the experiment. Following a 75- to 90-minute equilibration period, rings were contracted with phenylephrine (Phe) (1×10⁻⁷ mol/L in mesenteric artery or 1×10⁻⁵ mol/L in pulmonary artery, aorta, and human umbilical artery) and the presence of a functional endothelium was confirmed by eliciting a relaxant response (>95%) to acetylcholine (ACH) (1×10⁻⁵ mol/L), a dose that induces maximal SGC-mediated vasodilatation.⁷

After a further equilibration period of 30 to 45 minutes, vessels were contracted with a depolarizing solution (60×10⁻³ mol/L KCl) to obtain the maximal level of contraction. After further washing, the rings were allowed to equilibrate for at least 1 hour. Thereafter, they were again stimulated with Phe and concentration–response curves of relaxation to ACh (1×10⁻⁷ to 1×10⁻⁵ mol/L), bradykinin (Bk) (1×10⁻⁷ to 1×10⁻⁵ mol/L), or the slow-releasing NO donor diethylamine (DETA)-NO (1×10⁻⁸ to 1×10⁻⁴ mol/L) were carried out. In another set of experiments concentration–response curves of contraction to Phe (1×10⁻¹⁰ to 10⁻⁶ mol/L) were performed. The concentration (−log[mol/L]) that produced 95% of the maximal effect (pE⁰) was obtained by a nonlinear regression analysis with GraphPad software.

**Electrochemical Measurement of O₂ Consumption**

Aortic rings from 2 rats (80 to 100 mg total wet weight) or 3 mice (20 to 30 mg wet weight), pulmonary and mesenteric rings from 3 rats (15 to 25 mg wet weight), or human umbilical arteries (190±5 mg total wet weight) were placed in gas-tight containers containing 1 mL of Krebs solution and gently agitated at 37°C. The O₂ consumption by the tissue was measured with a Clark-type O₂ electrode (Rank Brothers, Bottisham, UK) calibrated with an air-saturated Krebs solution, assuming an [O₂] of 200×10⁻⁶ mol/L. Experiments were performed in the presence of the NO synthase inhibitor N°-nitro-l-arginine (L-NAA) (1×10⁻⁴ mol/L), the sGC inhibitor 1H-1,4-oxiazol[4,3-a]quinoxalin-1-one (ODQ) (5×10⁻⁶ mol/L), ACh (1×10⁻⁷ mol/L), Bk (1×10⁻⁵ mol/L), or Phe (1×10⁻⁵ mol/L) in mesenteric artery or 1×10⁻⁶ mol/L in pulmonary artery, aorta, and human umbilical artery) in intact or endothelium-denuded vessels. Sodium cyanide (1×10⁻⁶ mol/L) was used to confirm that O₂ consumption was mainly mitochondrial (≈95% to 99%).

In some experiments, the reversibility of NO-induced inhibition of respiration was assessed by adding oxyHb (1×10⁻⁵ mol/L) when the [O₂] in the chamber was 100×10⁻⁶ mol/L. Measurements were obtained using a data acquisition device, Duol8 (World Precision Instruments, Stevenage, UK). A hyperbolic function was used to describe the relationship between [O₂] and the rate of O₂ consumption (VO₂). The apparent O₂ affinity (Michaelis–Menten constant [Kₐ]) (1×10⁻⁶ mol/L) was calculated using the program GraphPad, and the results are shown in the Table. VO₂ was calculated at 2 specific [O₂], 130×10⁻⁶ mol/L and 30×10⁻⁶ mol/L, which were selected as representing those [O₂] present in arterial blood or within tissues, respectively.⁸ VO₂ was expressed as 1×10⁻⁹ mol O₂/min per milligram of protein. Proteins were determined by the BCA protein assay kit (Pierce, Rockford, III) using BSA as the standard.

In some cases, the viability of the rings was later assessed by confirming that their contractile response to Phe and their relaxant response to ACh did not differ from that of nonmanipulated vessels.

**Visualization of Intracellular O₂ by Fluorescence Microscopy**

Selected portions (∼1.5×1.5 cm) of the mesenteric arterial tree close to the gut were excised and incubated in the dark (3 hours) in Krebs solution (37°C) containing Tris(1,10-phenanthroline)rhuthenium(II) chloride hydrate [Ru(phen)₃²⁺] (1×10⁻⁴ mol/L). This fluorochrome has recently been adapted for use as an indicator of O₂ tension in cells and tissues, where its fluorescence is inversely proportional to the concentration of O₂.⁹,¹⁰ Ruthenium-based oxygen-sensing probes sense O₂ in the range of 0 to 9.1 ppm at 20°C, although their sensitivity range in tissues may differ at 37°C.¹¹ In addition to its strong visible absorption, efficient fluorescence, and relatively long-lived excited state, Ru(phen)₃²⁺ exhibits high O₂ sensitivity, a large Stoke shift, and high photo-chemical stability in the cellular environment. Because of its long emission wavelength the fluorescence signal of the indicator is shifted away from cellular autofluorescence, which causes serious perturbation when UV sensing indicators are used. In our experimental conditions, ruthenium is taken up by living cells and maintains its O₂-sensing properties for at least 5 hours after loading.

The vital cell nuclear stain Hoechst 33342 (1×10⁻⁵ mol/L, Bk (1×10⁻⁵ mol/L), DETA-NONO (1×10⁻⁵ mol/L), and Phe (1×10⁻⁵ mol/L) were used. In our experimental conditions, ruthenium is taken up by living cells and maintains its O₂-sensing properties for at least 5 hours after loading.

Samples were in treated with ACh (1×10⁻⁵ mol/L), Bk (1×10⁻⁵ mol/L), DETA-NONO (1×10⁻⁵ mol/L), and Phe (1×10⁻⁵ mol/L) in mesenteric artery or 1×10⁻⁶ mol/L in pulmonary artery, aorta, and human umbilical artery. In some cases, L-NA was added or the endothelium was removed [E(−)]. Data are means±SEM of 5–7 independent experiments. *P<0.05 vs control.
tems GmbH, Heidelberg, Germany). At least 70 cells were analyzed for each sample.

Further experiments were performed to exclude interference with Ru(phen)$_3$$^2$$^+$/H$_2$O$_2$ fluorescence by free radicals (H$_2$O$_2$) and NO (DETA-NO). Different concentrations (1$\times$10$^{-3}$ to 1$\times$10$^{-4}$ mol/L) of H$_2$O$_2$ and DETA-NO were incubated in the presence of Ru(phen)$_3$$^2$$^+$ (1$\times$10$^{-4}$ mol/L) in a cell-free Krebs solution. Fluorescence was measured with a Fluoroskan plate reader (Thermo Labsystems). Basal fluorescence was not modified by incubation with DETA-NO or H$_2$O$_2$, or either of the compounds in normoxia and hypoxia, except at a maximal concentration of H$_2$O$_2$ (1$\times$10$^{-4}$ mol/L) (n=4 to 5 experiments; results not shown).

Data Analysis

Unless otherwise stated, all results are the means$\pm$SEM of at least 5 experiments from different animals. Statistical analysis was performed by 1-way ANOVA (GraphPad Software) and Student–Newman–Keuls as a post hoc test. Significance was defined as $P<0.05$.

Drugs and Solutions

Phe, ACh, Bk, L-NA, sodium cyanide, ODQ, meth(a)emoglobin, Ru(phen)$_3$$^2$$^+$, and Hoechst 33342 were acquired from Sigma-Aldrich (St Louis, Mo). DETA-NO was from Alexis (Lausen, Switzerland). OxyHb was prepared by reduction of human meth(a)emoglobin with a 10-fold molar excess of sodium dithionite, followed by dialysis against PBS. All drugs were dissolved in ultrapure water. Ru(phen)$_3$$^2$$^+$ and Hoechst 33342 were dissolved in Krebs solution and ODQ was dissolved in DMSO (1:5000 vol:vol).

Results

Consumption of O$_2$ by Blood Vessels

First we monitored VO$_2$ in several isolated blood vessels when placed in an O$_2$-tight chamber, as previously described.7,9,10 Figure 1A and 1B show how the rat aorta gradually reduced its rate of O$_2$ consumption as the [O$_2$] decreased. The requirement of the tissue for O$_2$ was mainly mitochondrial because addition of sodium cyanide resulted in almost complete (95% to 99%) inhibition of O$_2$ consumption (data not shown). The reduction in the rate of consumption at low [O$_2$] was attenuated both by blocking NO synthesis with L-NA and by removal of the endothelium, indicating that NO was responsible for this effect and therefore for the observed increase in the apparent $K_m$ for O$_2$ (Figure 1B and the Table). This action of NO was independent of an effect on sGC because it was unaffected by treatment with the specific sGC inhibitor ODQ (Table).

Figure 1C shows the consumption of O$_2$ at 2 specific [O$_2$] that approximate to those of arterial blood (130$\times$10$^{-6}$ mol/L) and tissue (30$\times$10$^{-6}$ mol/L), respectively.7,8 Aortas were found to consume ~50% less O$_2$ at the lower of the 2 [O$_2$]. This NO-dependent adaptive response was not observed only in the aorta but in all the vessels studied, independent of species (human, rat, mouse) or anatomic origin (placental, systemic, or pulmonary circulation) (Table). In aortas from eNOS knockout mice, we observed a reduced apparent $K_m$ for O$_2$ and similar rates of O$_2$ consumption at the high and low [O$_2$] studied. This contrasted with the response of tissues from WT mice, which was similar to that of control rat aortas. The responses of tissues from the eNOS knockout mice were similar to those exhibited by WT controls after treatment with L-NA or endothelium denudation (Figure 1D through 1F).

Figure 1E shows the consumption of O$_2$ at 2 specific [O$_2$] that approach to those of arterial blood (130$\times$10$^{-6}$ mol/L) and tissue (30$\times$10$^{-6}$ mol/L), respectively.7,8 Aortas were found to consume ~50% less O$_2$ at the lower of the 2 [O$_2$]. This NO-dependent adaptive response was not observed only in the aorta but in all the vessels studied, independent of species (human, rat, mouse) or anatomic origin (placental, systemic, or pulmonary circulation) (Table). In aortas from eNOS knockout mice, we observed a reduced apparent $K_m$ for O$_2$ and similar rates of O$_2$ consumption at the high and low [O$_2$] studied. This contrasted with the response of tissues from WT mice, which was similar to that of control rat aortas. The responses of tissues from the eNOS knockout mice were similar to those exhibited by WT controls after treatment with L-NA or endothelium denudation (Figure 1D through 1F).

Treatment of rat arteries with vasodilators such ACh (1$\times$10$^{-5}$ mol/L) or Bk (1$\times$10$^{-5}$ mol/L) (EC$_{95}$) (see Materials and Methods) that stimulate endothelial NO generation resulted in a greater inhibition of O$_2$ consumption at the low [O$_2$] and, in addition, an inhibition of O$_2$ consumption at the
sels were treated with ACh (1 × 10⁻⁵ mol/L) or DETA-NO (1 × 10⁻⁶ mol/L) in endothelium-denuded vessels (E-) or following incubation with L-NA (1 × 10⁻⁴ mol/L). A shows the continuous measurement of VO₂, and B shows the VO₂ measured at 130 × 10⁻⁶ mol/L and 30 × 10⁻⁶ mol/L O₂. Data are means ± SEM from n=4 independent experiments, with *P<0.05 vs control at the corresponding O₂, and #P<0.05 vs the corresponding value at 130 × 10⁻⁶ mol/L O₂.

Figure 2. Effect of ACh and DETA-NO on VO₂ in rat aorta. Vessels were treated with ACh (1 × 10⁻⁵ mol/L) or DETA-NO (1 × 10⁻⁶ mol/L) in endothelium-denuded vessels (E-) or following incubation with L-NA (1 × 10⁻⁴ mol/L). A shows the continuous measurement of VO₂, and B shows the VO₂ measured at 130 × 10⁻⁶ mol/L and 30 × 10⁻⁶ mol/L O₂. Data are means ± SEM from n=4 independent experiments, with *P<0.05 vs control at the corresponding O₂, and #P<0.05 vs the corresponding value at 130 × 10⁻⁶ mol/L O₂.

higher [O₂] (Figure 2A and 2B and the Table). This did not occur when the tissues were treated with L-NA or were endothelium-denuded (Figure 2B). Unlike ACh or Bk, the greater inhibition of O₂ consumption and the increase in the Kₘ values induced by the slow-releasing NO donor DETA-NO (1 × 10⁻⁵ mol/L) were not significantly affected either by inhibition of NO production or by removal of the endothelium (Figure 2B). The fact that the potent vasoconstrictor Phe (EC₉₅) (1 × 10⁻⁶ mol/L in mesenteric artery or 1 × 10⁻⁶ mol/L in pulmonary artery, aorta and human umbilical artery) also induced an NO-dependent decrease in the vascular consumption of O₂ (Table) ruled out the possibility that the action of ACh, Bk, and DETA-NO was attributable to their vasodilator properties.

Concentration of O₂ in Vascular Tissue
We used the O₂ probe Ru(phen)₃⁺²⁺ (1 × 10⁻⁴ mol/L) to monitor O₂ concentrations under normal and hypoxic conditions in ex vivo portions of rat mesenteric tissue containing at least one blood vessel of ~20 to 30 μm in diameter. The tissue was placed on a purpose-built support inside a chamber and analyzed under a fluorescence microscope in continuously regulated conditions of temperature (37°C) and gas (5% CO₂ and variable concentrations of O₂), and images were obtained every 2 minutes. Following equilibration at 200 × 10⁻⁶ mol/L O₂ for 10 minutes, samples were subjected to hypoxia (~15 × 10⁻⁶ mol/L O₂) for 20 minutes by the addition of nitrogen. As shown in Figure 3A and 3B and the Movies and Figure I in the online data supplement (available at http://circres.ahajournals.org), in control experiments, this produced a rapid build up in the concentration of O₂ in the individual cells, as shown by a decrease in red fluorescence in their cytosol. This was not attributable to photobleaching by the camera because there was no change in the number of fluorescent cells if samples were maintained at 200 × 10⁻⁶ mol/L O₂ for 30 minutes. Furthermore, on cessation of hypoxia, fluorescence rapidly increased toward prehypoxic levels (data not shown). This effect of hypoxia on O₂ consumption did not occur following treatment with L-NA (Figure 3A and 3B and Online Movies), indicating that it was NO-dependent and that an active NO synthase was generating NO at concentrations sufficient to modulate the consumption of O₂, and divert it toward the surrounding tissues. This is supported by the fact that sodium cyanide, which also inhibits the CcO, produced a similar increase in the concentration of O₂ in the cells (see Online Movies).

Treatment with ACh further increased the build up of O₂ in hypoxia and the speed at which it occurred (Figure 3A and 3B and Online Movies). Thus, on induction of hypoxia, it took 6.40 ± 0.2 minutes to reduce by 50% the number of control fluorescent cells and only 5.20 ± 0.3 minutes in the presence of ACh. Administration of the same dose of ACh at 200 × 10⁻⁶ mol/L O₂ also elicited a decrease in ruthenium fluorescence that was smaller than that observed in hypoxia but was still significant (Figure 4A and 4B and Online Movies). This response was substantially enhanced if hypoxia was induced subsequently. Treatment with L-NA prevented the effects of ACh (Figure 4B) but had no effect on the similar response induced by DETA-NO (1 × 10⁻⁵ mol/L) (data not shown). Experiments in eNOS knockout mice further showed that, whereas mesenteric tissues from WT mice exhibited a similar NO-dependent increase in the concentration of tissue O₂ to that obtained in rats, those from eNOS knockout animals showed no changes in fluorescence during hypoxia (Figure 3A and 3C and Online Movies), even after the administration of ACh (data not shown).

Discussion
Our results indicate that both basal and stimulated release of NO from the vascular endothelium is responsible not only for the well-known regulation of vascular tone but also for the adjustment of O₂ consumption. In our experiments using isolated blood vessels, although we studied the consumption of O₂ over a wide range of [O₂], we chose to compare the behavior of the vessels at 2 [O₂], namely 130 × 10⁻⁶ mol/L and 30 × 10⁻⁶ mol/L, which approximate the [O₂] in arterial blood and tissues, respectively. Our results demonstrate that as the [O₂] decreased so did the consumption of O₂. In the absence of endothelium-derived NO, following inhibition of its synthesis with L-NA or removal of the endothelium, this adaptive change disappeared and the vascular consumption of O₂ remained constant over a wide range of [O₂]. There was eventually a drop in consumption in the absence of NO; however, this occurred at much lower [O₂].

This modulatory effect of NO was observed in a variety of vessels of different anatomical origin and sources, including human, and is consistent with its known effect in reducing the
affinity of CcO for O₂ in a competitive manner, i.e., increasing its $K_m$ and adjusting mitochondrial O₂ consumption.⁸,¹⁵ We found that aortas from eNOS knockout mice exhibited a reduced $K_m$ for O₂ and consumed equal amounts of O₂ independently of the [O₂] in the medium, further indicating that endothelium-derived NO is responsible for regulating O₂ consumption.

When endothelial NO generation was increased with ACh or Bk, at concentrations at which these agonists produced potent sGC-mediated vasodilation,¹⁶ there was an enhanced reduction in VO₂. This occurred even at the higher [O₂] and was also prevented by treatment with L-NA or removal of the endothelium. Administration of exogenous NO with DETA-NO also induced a greater inhibition of O₂ consumption and increase in $K_m$, which were not affected either by inhibition of NO generation or by removal of the endothelium. These results are in accordance with previous observations in cells³,⁹ and in tissues.⁴,⁷,¹⁷ This NO-dependent effect on consumption of O₂ was also observed in the presence of the vasoconstrictor Phe, which is known to release NO following activation of endothelial $\alpha_1$ adrenoreceptors.¹⁸

Inhibition of CcO by NO (a phenomenon that has been called “metabolic hypoxia”⁸) leads to a major redistribution of O₂, which has been demonstrated in cells in culture.⁶,¹⁹ Our results, obtained with fluorescence microscopy show that this redistribution also occurs in vascular tissues in vitro. Indeed, these experiments show that the stimulation of endothelial NO production with ACh resulted in an increase in the intracellular [O₂] of the mesenteric cells surrounding a microvessel, as shown by the decrease in fluorescence of Ru(phen)$_2^{2+}$. This effect could be observed even in experiments carried out at 200×10⁻⁶ mol/L O₂, in which ACh was able to generate enough NO to modulate O₂ consumption. Addition of DETA-NO and other inhibitors of mitochondrial respiration to the vascular preparations also led to an increase in the intracellular [O₂], indicating a concentration-dependent

---

**Figure 3.** Changes in intracellular [O₂] in rat and mice mesenteric cells, in close proximity to a blood vessel, when exposed to hypoxia. The preparation was loaded with Ru(phen)$_2^{2+}$ (3 hours, 1×10⁻⁴ mol/L, red fluorescence), whose fluorescence is inversely proportional to the [O₂]. Following a 10-minute equilibration period at atmospheric [O₂] (200×10⁻⁶ mol/L O₂), samples were subjected to hypoxia (15×10⁻⁶ mol/L O₂) for a 20-minute period by the addition of nitrogen in the presence or absence of L-NA (1×10⁻⁴ mol/L), ACh (1×10⁻⁶ mol/L), or DETA-NO (1×10⁻⁷ mol/L). Fluorescence in individual cells was monitored at 2 minutes intervals following hypoxia, as shown in A, where phase-contrast images of the selected area are shown (left), and the arrows show the blood vessels. B and C show the changes in Ru(phen)$_2^{2+}$ fluorescence intensity expressed as a percentage of basal fluorescence. Data are means±SEM from 5 independent experiments and *P<0.05 vs value at 200×10⁻⁶ mol/L O₂ (time 0). Bar=100 μm.

---

**Figure 4.** Effect of ACh on intracellular [O₂] in rat mesenteric cells, in close proximity to a blood vessel. The preparation was loaded with Ru(phen)$_2^{2+}$, as described in the legend to Figure 3. Following 10 minutes of equilibration at 200×10⁻⁶ mol/L O₂, ACh (1×10⁻⁶ mol/L) was added for a further 10 minutes, and samples were then subjected to hypoxia (15×10⁻⁶ mol/L O₂) for 10 minutes in the presence or absence of L-NA (1×10⁻⁴ mol/L). Fluorescence in individual cells was monitored at 2-minute intervals, as shown in A and B. B shows the changes in Ru(phen)$_2^{2+}$ fluorescence intensity expressed as a percentage of basal fluorescence. Data are means±SEM from 5 independent experiments and *P<0.05 vs value at 200×10⁻⁶ mol/L O₂.
effect of NO. The reason for the paradoxical increase in cellular $[O_2]$ when exposed to hypoxia is that in normoxia, where $O_2$ consumption is high, there is a steep $O_2$ gradient toward $O_2$-consuming mitochondria, leaving a relatively low level of spare $O_2$ (hence high ruthenium fluorescence). In hypoxia, NO-dependent inhibition of respiration leads to decreased $O_2$ consumption and thus a paradoxical increase in the levels of available $O_2$ (hence a lower number of ruthenium fluorescent cells).

In conclusion, our results indicate that the basal release of endothelial NO adjusts vascular $O_2$ consumption. This may occur at the level of the microcirculation to facilitate the distribution of $O_2$ to the tissues, especially at low $[O_2]$, as has been indicated before.6,20,21 It may also occur in the larger vessels, where the requirement for $O_2$ by the vascular smooth muscle may vary as a result of the action of hormones such as ACh and adrenaline, as well as the activity of the different sets of nerves that innervate the vasculature. This remains to be studied. In addition, it is possible that changes in the distribution of $O_2$ throughout the vessel wall, because of a decrease in NO production in endothelial dysfunction, may play a role in the development of vascular disease.

Acknowledgments
We thank Annie Higgs and Brian Normanly for help with manuscript preparation and Eoin Cummins for assistance with imaging.

Sources of Funding
This study was supported by Ministerio de Educacion y Ciencia (Spain) grant PI07/0091 and Contrato-Investigador Fondo de Investigacion Sanitaria (FIS) grant CP07/00171 (to V.M.V.). J.V.E. is the recipient of Ministerio de Educacion y Ciencia (Spain) grants SAF 2005-01366 and PI08/1325, and P.D. is the recipient of Ministerio de Educacion y Ciencia (Spain) grant SAF 2004-01541. C.T.T. is the recipient of a grant from the Science Foundation Ireland. S.M. is supported in part by the European FP6 (LSHM-CT-2004-005033).

Disclosures

Legend for supplementary films.

Hypoxia-induced changes in intracellular [O$_2$] in rat and mouse mesenteric cells in close proximity to a blood vessel. The preparation was loaded with Ru(phen)$_3^{2+}$ (3h, 1X10$^{-4}$ mol/L µM, red fluorescence), whose fluorescence is inversely proportional to the [O$_2$]. Fluorescence was filmed for a 20 min period in normoxia or hypoxia, recording one frame every 2 min. When tissues were subjected to hypoxia following normoxia, the first frame was taken in normoxia and the subsequent frames in hypoxia. (A) Control normoxia, (B) control hypoxia, (C) hypoxia in the presence of L-NA, (D) hypoxia in the presence of ACh, (E) hypoxia in the presence of DETA-NO, (F) normoxia in the presence of cyanide, (G) hypoxia in cells from eNOS $^{-/-}$ mice, (H) addition of ACh in the presence of normoxia, and (I) hypoxia in the presence of ACh.

Online Figure I.

Representative images of cells from the mesenterium showing the changes that took place in intracellular [O$_2$] when exposed to hypoxia (nucleus stained with Hoescht (blue), O$_2$ stained with Ru(phen)$_3^{2+}$ (red) in the cytosol of the cells). The preparation was loaded with Ru(phen)$_3^{2+}$ (3h, 1X10$^{-4}$ mol/L, red fluorescence), whose fluorescence is inversely proportional to the [O$_2$]. The vital cell nuclear stain Hoechst 33342 (1X10$^{-6}$ mol/L) was added for the last 30 min of incubation. Following a 10 min equilibration period at atmospheric [O$_2$] (200X10$^{-6}$ mol/L O$_2$), samples were subjected to hypoxia (15X10$^{-6}$ mol/L O$_2$) for a 20 min period by the
addition of nitrogen. The panels on the left show the merged fluorescence of Hoescht (blue) and Ru(phen)$_3^{2+}$ (red) while the panels on the right show Ru(phen)$_3^{2+}$ alone.
