photoreceptor death

1. Introduction

Inherited retinal degeneration affecting both rod and cone photoreceptors constitutes one of the causes of incurable blindness in the developed world. Cyclic guanosine monophosphate (cGMP) is crucial in the phototransduction and mutations in genes related to its metabolism are responsible for different retinal dystrophies. cGMP-degrading phosphodiesterase 6 (PDE6) mutations cause around 4–5% of the retinitis pigmentosa, a rare form of retinal degeneration. The aim of this study was to evaluate whether pharmacological PDE6 inhibition induced retinal degeneration in cone-enriched cultures of porcine retina similar to that found in murine models. PDE6 inhibition was induced in cone-enriched retinal explants from pigs by Zaprinast. PDE6 inhibition induced cGMP accumulation and triggered retinal degeneration, as determined by TUNEL assay. Western blot analysis and immunostaining indicated that degeneration was accompanied by caspase-3, calpain-2 activation and poly (ADP-ribose) accumulation. Oxidative stress markers, total antioxidant capacity, thiobarbituric acid reactive substances (TBARS) and nitric oxide measurements revealed the presence of oxidative damage. Elevated TNF-alpha and IL-6, as determined by enzyme immunosassay, were also found in cone-enriched retinal explants treated with Zaprinast. Our study suggests that this ex vivo model of retinal degeneration in porcine retina could be an alternative model for therapeutic research into the mechanisms of photoreceptor death in cone-related diseases, thus replacing or reducing animal experiments.

conjugated again to opsins to form a new, functional visual pigment.

Rods and cones recover from excitation and recover their light-sensitivity by both inactivating the PDE6 cascade and synthesizing new cGMP by Ca2+-sensitive membrane guanylyl cyclases (RetGCs). RetGCs are controlled by a calcium negative feedback through Ca2+/ Mg2+ binding proteins, GCAPs (guanylyl cyclase activating proteins) (Burns et al., 2002; Koch and Stryer, 1988). Alterations in any step of the phototransduction cascade could lead to photoreceptor cell death.

Cyclic GMP is essential for the ability of rods and cones to respond to the light stimuli and the control of its level is critical for proper functioning of photoreceptors. Mutations in genes involved in cGMP synthesis (RetGCs and GCAPs) or degradation (PDE6) (Chang et al., 2009; Dizhoor, 2000; Grau et al., 2011; Piri et al., 2005; Hunt et al., 2010) can lead to various forms of retinal dystrophies such as some types of retinitis pigmentosa (Bowes et al., 1990; McLaughlin et al., 1993), progressive cone dystrophy (Thiаденс et al., 2009), dominant cone degeneration (Behnen et al., 2010; Jiang and Baehr, 2010), cone-rod dystrophy (Buch et al., 2011; Sokal et al., 2005; Tucker et al., 1999) and Leber congenital amaurosis (Perrault et al., 2000, 1996).

Retinitis Pigmentosa (RP) is a common form of rod-cone dystrophy, constituting the largest Mendelian genetic cause of blindness in the developed world. Patients with RP typically lose night vision in adolescence, peripheral vision in young adulthood, and central vision later in life due to progressive loss of rod and cone photoreceptor cells. Photoreceptor cell death starts with rod photoreceptor degeneration and eventually cone cell death that is the major problem affecting RP patients, because it leads to loss of central vision (Kalloniatis and Fletcher, 2004).

Mutations in genes encoding α and β-subunit of PDE6 have been reported to cause recessive RP in humans (Corton et al., 2010; Dryja et al., 1999; Huang et al., 1995; McLaughlin et al., 1995). PDE6α, PDE6ß-631 and PDE6δ-610 mice are models of human autosomal recessive RP that carry mutations on the α or the β-subunit of PDE6 (Bowes et al., 1990; Chang et al., 2002), that triggers photoreceptor degeneration (Farber and Lolley, 1974; Paquet-Durand et al., 2009). Others than the available murine models have been reported to carry mutations in PDE6 subunits such as the canine models rcd1 and rcd2 (Petersen-Jones et al., 1999; Sargan et al., 1994; Suber et al., 1993; Tuntivanich et al., 2008; Wang et al., 1999).

Although murine models provide invaluable information about photoreceptor cell death, they present different eye size and anatomic differences in retinal structures compared to humans; for example, they lack macula and fovea. This is why the use of large animal models seems to be critical for the development of retinal therapies (Perrault et al., 2000, 1996).

This study investigated whether PDE6 inhibition produced ex vivo retinal degeneration in cone-enriched cultures of porcine retina similar to the degeneration found in murine models of RP with non-functional PDE6. Secondly, we assessed whether the damage was accompanied with oxidative stress and induction of inflammatory mediators.

We found that PDE6 inhibition triggered retinal degeneration with caspase-3, calpain-2 activation and PAR accumulation (indicator of PARP activity) and induced oxidative stress and cytokine induction in cone-enriched cultures of porcine retina. These results suggest that the cone-enriched organotypic culture of porcine retina exposed to PDE inhibitor could be a complementary model for therapeutic research into the mechanisms of retinal degeneration, thus replacing or reducing animal experiments.

2. Materials and methods

2.1. Porcine retinal explant cultures

Sixty eyes (both left and right eye) from small miniature pigs 3–7 months old were obtained from the local slaughterhouse. Neuroretina explants enriched in cones were carried out as previously described (Fernandez-Bueno et al., 2008) with some modifications. Briefly, each eyeball was immersed in 70% ethanol and washed in Dulbecco’s Modified Eagle Medium (DMEM). All extraocular tissues were removed and the sclera was punctured with a 22 gauge needle at the ora serrata and bisected, dividing the ocular globe into anterior and posterior eye cups. The vitreous was removed, and the posterior eye cup was placed into a dish with phosphate buffer saline (PBS). A paintbrush was used to mechanically detach the neuroretina from the RPE, and the optic nerve was cut with Westcott scissors. The visual streak with a high cone density (Hendrickson and Hicks, 2002) was cut into 5 × 5 mm explants. Explants were transferred to Transwell® culture dishes (Corning Inc., Corning, NY) with photoreceptor side down, containing 1.5 mL culture medium composed of Neurobasal A medium supplemented with 2% B-27 (Invitrogen, Life Technologies, Madrid, Spain), 2 mM l-glutamine (Invitrogen, Life Technologies, Madrid, Spain), 100 U/mL penicillin, and 100 ng/mL streptomycin (Invitrogen, Life Technologies, Madrid, Spain). Explants were cultured at 37 °C with 5% CO2 in a humidified atmosphere. The culture medium level was maintained in contact with the support membrane beneath the explant.

Treatments were added the day of the culture and maintained them for 24 h or 48 h.

To evaluate the effect of PDE6 inhibition we used Zaprinast (Zhang et al., 2005) (100, 200 and 500 mM/L), Zaprinast (Sigma–Aldrich, Madrid, Spain) was prepared in dimethyl sulfoxide (DMSO) (AppliChem, Darmstadt, Germany). For controls, the same amount of DMSO was added to the culture medium. Some retinal explants were also exposed to 2 μmol/L A231187, a calcium ionophore, as apoptotic inducer (Sigma–Aldrich, Madrid, Spain).

Freshly detached neuroretinas were also obtained for normal morphologic and biochemical evaluation.

2.2. Tissue processing and histology

For morphological characterization retinal explants were fixed in 4% filtered paraformaldehyde (Sigma–Aldrich, Madrid, Spain) and 5% glutaraldehyde (Electron Microscopy Sciences, Hatfield, UK) in 0.1 M PBS (pH 7.4) for 2 h. Afterwards explants were post-fixed with 2% osmium tetroxide, rinsed, dehydrated and embedded in Durcupan resin (Fluka, Sigma–Aldrich, Madrid, Spain). Semi-thin sections were cut at 1.5 μm, mounted on gelatin-coated slides and stained with 1% toluidine blue. These sections were examined under an Eclipse 80i microscope (NIKON Instruments, Badhoevedorp, The Netherlands) and images were captured with a DS-Qi1 digital camera (NIKON Instruments, 2013).
Badhoevedorp, The Netherlands). ImageJ software was used to quantitate the number of retinal explants. After calibration, total area of at least three visual fields per retinal explant was calculated. The total area was expressed as μm². Data are expressed as mean ± SEM.

To evaluate apoptosis with the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay, retinal explants were fixed in 4% filtered paraformaldehyde (Sigma–Aldrich, Madrid, Spain) in 0.1 M PBS (pH 7.4) and cryoprotected in a sucrose gradient (15–20–30%) (Panreac Quimica, Barcelona, Spain). Samples were frozen embedded in Tissue-Tek ® O.C.T. ™ Compound (Sakura Finetek Europe B.V., Zoeterwoude, The Netherlands). Next, 10 μm sections were cut with a cryostat (Leica CM1900, Nussloch, Germany) and placed on Super Frost Ultra Plus treated slides (Thermo Scientific, Barcelona, Spain).

2.3. TUNEL assay

The TUNEL assay was performed on 10 μm cryosections by means of an in situ cell death detection kit conjugated with rhodamine fluorochrome (ApopTag Red In Situ) (Millipore, Schwalbach, Germany) according to the manufacturer’s instructions. The specimens were examined under an Eclipse 80i microscope (NIKON Instruments, Badhoevedorp, The Netherlands) and images were captured with a DS-Qi1 digital camera (NIKON Instruments, Badhoevedorp, The Netherlands). The apoptotic (TUNEL-positive) nuclei per visual field were counted in at least three visual fields per each retinal explant using NIS-Elements imaging software (NIKON Instruments, Badhoevedorp, The Netherlands). The apoptotic (TUNEL-positive) nuclei per visual field were counted in at least three visual fields per each retinal explant using NIS-Elements imaging software (NIKON Instruments, Badhoevedorp, The Netherlands). The number of apoptotic nuclei was expressed as mean ± SEM.

2.4. Immunofluorescence of Caspase-3 and PAR

Immunofluorescence was carried out on 10 μm cryosections. Sections were post-fixed for 15 min at room temperature in 4% filtered paraformaldehyde (Sigma–Aldrich, Madrid, Spain) in 0.1 M PBS (pH 7.4). Sections were incubated for 1 h in blocking solution containing 5% normal goat serum, 1% bovine serum albumin and 0.25% Triton X-100. They were then incubated with primary antibody against cleaved Caspase-3 (1:200, Cell Signaling Technology, Barcelona, Spain) or PAR (poly-(ADP-ribose) (1:200, Enzo Life Science, Madison, Spain) overnight at 4 ˚C in blocking solution. After washing with PBS three times, samples were incubated for 1 h at room temperature with the fluorescence-conjugated secondary antibody Alexa Fluor 647 (Invitrogen, Life Technologies, Madrid, Spain). After washing with PBS three times, sections were observed under a confocal microscope (Leica TCS SP5 Confocal microscope, Leica Microsystems S.L.U, Barcelona, Spain). SYTOX Green (Molecular Probes, Paisley, UK) were used as a counterstain for the nuclei. For co-localization with cleaved caspase-3 or PAR, staining was performed following the manufacturer’s instructions (Bio-Vision, Mountain View, CA). Total retinal protein was extracted from retinal explants and measured by the BCA protein assay. Caspase-3 activity was expressed as arbitrary units (au)/mg of protein.

2.5. Cyclic GMP determination

cGMP was measured by using the BIOTRAK cGMP enzyme immunoassay kit (GE Healthcare Europe GmbH, Barcelona, Spain). Retinal explants were homogenised in 5% trichloroacetic acid and neutralized with 2 M potassium bicarbonate. Neutralized supernatant was used for cGMP determination. Protein content was measured by the bicinchoninic acid (BCA) protein assay (BCA Kit; Pierce Scientific, CA). The tissue cGMP levels were expressed as pmol/mg protein.

2.6. Caspase-3 activity assay

Caspase-3 activity was measured with a colorimetric tetrapeptidyl (DEVD-pNA) cleavage assay kit following the manufacturer’s instructions. Total retinal protein was extracted from retinal explants and measured by the BCA protein assay. Caspase-3 activity was expressed as arbitrary units (au)/mg of protein.

2.7. Nitrites and nitrates (NOX) determination

Intracellular and extracellular nitrites (stable end-product of NO) and nitrates (NOX) were measured in retinal explants by spectrophotometric GRIESS reaction (El-Milili et al., 2008) using nitrate reductase. The tissue NOX levels were expressed as nmol/mg protein (intracellular) or nmol/mL (extracellular).

2.8. Oxidative stress evaluation

Retinal explants were assayed for total antioxidant capacity (TAC) and thiobarbituric acid reactive substances (TBARS) formation as indicator of malonyldialdehyde (MDA) formation. Retinal explants were homogenized in 5 mM phosphate buffer pH 7, 0.9% NaCl, 0.1% glucose, centrifuged at 10,000 × g for 15 min at 4 ˚C, and then the supernatants were used to determine TAC and TBARS. Protein concentrations were measured by the BCA protein assay. TAC was measured using a commercial kit (Cayman Chemical, Chemical, Ann Arbor, MI) (Kowluru et al., 2006). The tissue TAC levels were expressed as nmol/mg protein.

MDA levels were detected by a colorimetric method involving thioarbituric acid (TBA) adduct formation (Cayman Chemical, Chemical, Ann Arbor, MI). Tissue TBARS levels were expressed as nmol/mg protein.

2.9. TNF-alpha and IL-6 measurement

For detection of cytokine levels, retinal explants were homogenized in 20 mM Tris–HCl pH 7.4, 10 mM EDTA containing protease inhibitor cocktail (Complete Protease Inhibitor Cocktail; Roche, Basel, Switzerland) and 200 μM phenylmethylsulfonyl fluoride (PMSF). The TNF-α and IL-6 protein levels were estimated with the corresponding ELISA kit (Diaclone, Besancon, France), according to the manufacturer’s instructions. Tissue cytokine levels were expressed as pg/mL protein.

Values for cGMP, caspase-3 activity, NOX, oxidative markers and cytokines are given as the mean ± SEM of at least ten different cultures. For each experiment samples were measured in duplicate.
2.10. Western blot

Retinal explants were homogenized in lysis buffer (50 mM Tris–HCl buffer pH 7.4 containing 50 mM NaCl, 5 mM EDTA, 1% SDS, protease inhibitor cocktail (Complete Protease Inhibitor Cocktail; Roche, Basel, Switzerland) and 1 mM PMSF). Samples (30 μg) were subjected to electrophoresis and immunoblotting as described in Corbalán et al. (2002). The following primary antibodies were used: cleaved caspase-3 (Asp175) rabbit polyclonal antibody (1:1000; Cell Signaling Technology, Danvers, MA, USA), calpain-2 rabbit polyclonal antibody (1:1000; Sigma–Aldrich, Madrid, Spain); and β-actin mouse monoclonal antibody (1:2000; Sigma–Aldrich, Madrid, Spain). The images were captured using an EPSON SCAN from EPSON Corporation (EPSON IBERICA, Barcelona, Spain) and quantified using the Alpha Imager 2200 (version 3.1.2) software (Alphalnotech Corporation, San Francisco, CA, USA).

2.11. Statistical analyses

For parametric data, ANOVA followed by Newman–Keuls post-hoc test was used. When only two samples were compared the Student’s t-test was used.

For non-parametric data, Mann–Whitney test was used. Significance levels were set at α = 0.05.

3. Results

3.1. PDE inhibition triggers cGMP accumulation in cultured porcine retina

Retinal explants were cultured for 48 h in the presence or absence of Zaprinast, a selective PDE5/6 inhibitor which raises intracellular cGMP levels in a concentration-dependent manner and causes cGMP-dependent photoreceptor degeneration in small animals closely resembling the rd1 degeneration (Sahaboglu et al., 2010).

Successful PDE6 inhibition was confirmed by a significant cGMP increase at all time points evaluated (Fig. 1). While untreated retina essentially maintained the same level of cGMP, the Zaprinast-treated retina showed a strong increase of cGMP accumulation at 24 h in a dose-dependent manner (1.72 ± 0.3; 2.04 ± 0.2, 2.78 ± 0.27 pmol/mg protein at 100, 200 and 500 nmol/L respectively, One-way ANOVA post-hoc Newman–Keuls p < 0.05). Under our experimental conditions, the effect of Zaprinast concentration on cGMP accumulation disappeared at 48 h.

100 nmol/L Zaprinast was the lowest concentration that induced a significant cGMP accumulation at 24 h and 48 h. In view of these results, 100 nmol/L seemed to be the best concentration of Zaprinast for further studies.

3.2. Evaluation of organotypic retina cultures

To evaluate the overall architecture of the cultured retina was maintained throughout the culture period (Fig. 2A). However, morphometric analysis revealed that explants treated with 100 nmol/L Zaprinast were significantly thinner (47.915 ± 2938 μm², Mann–Whitney test, p < 0.01 and 33.129 ± 1365 μm², Mann–Whitney test, p < 0.05), compared with controls (58.940 ± 861 μm² and 42.000 ± 2220 μm²) at 24 h and 48 h respectively (Fig. 2B). Zaprinast also decreased photoreceptor outer segments (OS) compared to control explants (Fig. 2A).

3.3. PDE inhibition induces apoptosis in cultured porcine retina

The TUNEL assay was performed to measure the apoptotic cell death in fresh isolated retinas, control explants and explants treated with different Zaprinast concentrations (Fig. 3). While fresh isolated retina did not present any apoptotic nuclei, control explants showed a few apoptotic nuclei (2.4 ± 0.7% of TUNEL-positive cells) after 24 h in culture.

TUNEL staining demonstrated that inhibition of PDE induced photoreceptor degeneration overall after 48 h of Zaprinast treatment. As shown in Fig. 3A and Table 1, apoptotic nuclei were found in outer nuclear layer (ONL), in inner nuclear layer (INL) and also in the ganglion layer (GCL) at the lower dose of Zaprinast (100 nmol/L). The major effect was observed in ONL (4.6 ± 1.3% of apoptotic cells, Mann–Whitney test, p < 0.0001). Moreover, Zaprinast caused significant increase of TUNEL-positive cells (ANOVA test, post-hoc Newman–Keuls, p < 0.05) after 24 h in a concentration-dependent manner (Fig. 3B).

As shown in Fig. 3 control explants showed low numbers of TUNEL-positive cells after 24 h in culture (2.4 ± 0.7% of apoptotic cells) but this number increased across the whole retinal explant (ONL, INL and GCL) after 48 h (6.7 ± 1.0% of apoptotic cells). This cell death was consequence of retinal detachment and culturing time.

To further investigate the impact of PDE inhibition on downstream effectors of cell death, we analysed the activity of caspase-3, and activation of calpain-2.

After 24 h, caspase-3 activity (Fig. 4A) and protein content of cleaved caspase-3 (Fig. 4B) were further up regulated in retina treated with 100 nmol/L Zaprinast (2.4 ± 0.1 au/mg protein and 2.1 ± 0.4 fold over control retina respectively, student t-test, p < 0.05). This up regulation was maintained at 48 h (2.4 ± 0.2 au/mg protein and 2.7 ± 0.8 fold over control retina, student t test, p < 0.05). Immunofluorescence of cleaved caspase-3 revealed that PDE inhibition significantly up regulated caspase-3 in INL (2.6 ± 0.3% of caspase-3 positive cells, p < 0.0005) and GCL (1.7 ± 0.2% of caspase-3 positive cells, p < 0.01) but not in ONL (0.3 ± 0.1% of caspase-3 positive cells), after 24 h in culture (Table 1 and Fig. 4C). Control explants also showed up regulation of caspase-3 mainly in GCL after 48 h.

Western blot analysis showed that PDE6 inhibition also induced calpain-2 activation (Fig. 4D). A Ca²⁺ ionophore, A231878, was used to confirm calpain-2 activation.

Strong activation of poly(ADP-ribose) polymerase (PARP) has been found in animal models of retinal degeneration with subsequent accumulation of poly(ADP-ribose) (PAR) polymers (Paquet-Durand et al., 2007; Kaur et al., 2011). Excessive PARP activation may contribute to caspase-independent photoreceptor death (Paquet-Durand et al., 2007; Kaur et al., 2011). To investigate indirectly PARP activity in Zaprinast-treated explants, we...
performed PAR immunostaining. PDE6 inhibition significantly increased accumulation of poly(ADP-ribosyl)ated proteins in ONL (23,744 ± 5304 corrected fluorescence, Mann–Whitney test, p < 0.05) compared to control (7497 ± 722 corrected fluorescence) after 24 h in culture (Table 1). To determine whether cleaved caspase-3 or PAR co-localize with TUNEL-positive cells, we performed double labelling (Fig. 5). In Zaprinast-treated explants PAR immunostaining co-localized to a large extent with TUNEL-positive cells in GCL and ONL. A few number of cells in INL also co-localized with PAR. However, caspase-3 positive cells did not co-localize with TUNEL-positive cells except for a subset of cells in INL. Moreover, double-immunostaining of caspase-3 and PAR reflected co-localization in a subset of cells in GCL and INL. Caspase-3 activation occurs mainly in INL and it may partially contribute to cell death in this cell layer. Moreover, caspase-3 activation also occurs in GCL and could contribute to the future cell death.
death. Taking together, these results suggest that PDE6 inhibition probably induces cell death by caspase-independent mechanisms (PARP activity) in ONL and GCL and by caspase-dependent and caspase-independent mechanisms in INL.

3.4. PDE inhibition induces oxidative stress and cytokine production in cultured porcine retina

It has been described that cGMP accumulation induces oxidative stress in murine models of retinal degeneration (Sharma and Rohrer, 2007). To explore whether PDE inhibition also induced oxidative damage in cultured porcine retina we measured: intracellular and extracellular nitrites formation (iNOX and eNOX) as measurement of nitric oxide, TBARS formation as indicator of lipid peroxidation and total antioxidant capacity (Fig. 6).

At 24 h, PDE6 inhibition enhanced iNOX levels compared with control (48 ± 4 nmol/mg protein and 30 ± 2 nmol/mg protein, respectively, student t-test, \( p < 0.05 \)). As culturing time moved forward eNOX level also increased compared to control (47 ± 3 nmol/mL and 36 ± 2 nmol/mL, respectively, student t-test, \( p < 0.05 \)) (Fig. 6A).

MDA concentration was determined by the thiobarbituric acid (TBA) assay, which measures the amount of TBA reactivity with MDA formed during the acid hydrolysis of lipid peroxide compound. Addition of 100 nmol/L Zaprinast caused a rapid increase of lipid peroxide TBA value compared with control at 24 h

Fig. 4. PDE6 inhibition activates caspase-3 and calpain-2 in cone-enriched cultures of porcine neuroretina. Control retinal explants or Zaprinast-treated retinal explants were prepared as described in Materials and methods. (A) Caspase-3 activity using the substrate DEVD-pNA in homogenates of control retinal explants or explants treated with Zaprinast (100 nmol/mL). Values are the mean ± SEM of twelve cultures. (B and D) Retinal homogenates (30 μg of protein) were subjected to electrophoresis and cleaved caspase-3 (B) and calpain-2 (D) activation were analysed by immunoblotting. The intensities of the bands were quantified (paired student t-test). The values are represented as fold over control. Values significantly different from own control are indicated by asterisks *p < 0.05. (paired student t-test), (C) Evaluation of caspase-3 activation with cleaved caspase-3 staining in frozen sections; scale bar, 50 μm.

(3.9 ± 0.4 nmol/mg protein and 2.0 ± 0.2 nmol/mg protein, student t-test, p < 0.05), remaining elevated at 48 h (4.8 ± 0.5 nmol/mg protein, student t-test, p < 0.05 (Fig. 6B)).

The overall antioxidant capacity of retinal explants treated with 100 nmol/L Zaprinast, decreased at 24 h and 48 h (174 ± 12 μmol/mg protein and 156 ± 9 μmol/mg protein respectively, student t-test, p < 0.05), compared to control retinal explants (225 ± 21 μmol/mg protein and 192 ± 14 μmol/mg protein, respectively) (Fig. 6B).

TNFα and IL-6 are upregulated in several inflammatory ocular diseases, including Adamantiades–Behcet disease (Durrani et al., 2007), retinal vascular tumours (Japiassú et al., 2008), neovascular age-related macular degeneration (Seddon et al., 2005), uveitis (Murray et al., 1990), and retinitis pigmentosa (Yoshida et al., 2013a,b). We assessed whether 100 nmol/L Zaprinast induced these pro-inflammatory mediators in porcine retinal explants (Fig. 6C).

PDE inhibition induced a significant long-lasting upregulation of TNF-alpha at 24 h and 48 h (49.6 ± 10.2 pg/mg protein and 50.8 ± 5.6 pg/mg protein, respectively, student t-test, p < 0.05) compared to control (26.6 ± 3.6 pg/mg protein and 24.5 ± 2.9 pg/mg protein, respectively).

At 24 h PDE inhibition also produced IL-6 up regulation (6.5 ± 1.8 pg/mg protein, student t-test, p < 0.05) compared to control (3.1 ± 0.4 pg/mg protein).

4. Discussion

Mutations in genes related to cGMP metabolism as RetGC, GCAPs or PDE6 are involved in several retinal dystrophies including retinitis pigmentosa. Between 4 and 5% of patients with retinitis pigmentosa present PDE6 mutations leading to non-functional enzyme.

There is a lot of interest in using the pig as a model of retinal disease and stem cell transplantation therapy due to its resemblance to human retina. However, transgenic pigs are expensive and difficult to manage. Porcine organotypic culture of the retina is a choice that could allow us to evaluate the effect of new therapeutic drugs on some retinal changes faster and cheaper than in vivo and has the additional advantage of reducing animal experiments. These organotypic cultures were originally developed to follow cellular and cytoskeletal changes during the culture period (Allamby et al., 1997; Winkler et al., 2002) and more recently to study retinal detachment (Fernandez-Bueno, 2008; Fisher and Lewis, 2003). Here we evaluated whether PDE6 inhibition produced retinal degeneration in enriched-cone cultures of porcine retina.

Firstly, we assessed whether this porcine model reproduces the retinal degeneration observed in small animals after PDE inhibition. Our results showed that PDE inhibition induced cGMP accumulation accompanied by retinal degeneration. These results corroborated those found in small animals both in vivo and in vitro (Sahaboglu et al., 2010; Vallazza-Deschamps et al., 2005). Sahaboglu et al. (2010) demonstrated that Zaprinast caused cGMP-dependent photoreceptor degeneration closely resembling the rd1 degeneration observed in murine retinal explants. In the rd1 mouse the high levels of cGMP increase the number of the cGMP-gated channels in the open state, thus allowing intracellular calcium...
(Ca^{2+}) to rise to toxic levels and leading to rapid photoreceptor degeneration (Fox et al., 1999). Several studies have pursued to reverse the effects of PDE6 loss function by blocking cGMP-gate channel (Vallazza-Deschamps et al., 2005), Ca^{2+} channel (Nakazawa, 2011) or PKG activity (Paquet-Durand et al., 2009). All these treatments reduced photoreceptor cell death.

We reported that sustained elevation of intracellular cGMP in porcine retinal explants triggered different downstream effectors of cell death related to caspase-dependent mechanisms (caspase-3) and caspase-independent mechanisms (calpain-2 and probably PARP activity, measured as PAR accumulation). In 661W cells inhibition of PDE, increases the intracellular Ca^{2+} that in turns activates the cysteine protease calpain, which executes apoptosis via modulation of caspase-3 activity (Sharma and Rohrer, 2004). Caspase activation occurs mainly through the extrinsic and intrinsic pathways (Bredesen et al., 2006). Although caspase-3 inhibitors have been transiently effective in delaying retinal degeneration through inhibition of the apoptosis of photoreceptor cells in rd gene-carrying mice (Yoshizawa et al., 2002), the role of caspas in inherited retinal degeneration is controversial (Doonan et al., 2003; Sanges et al., 2006; Zeiss et al., 2004). Recent studies have shown that several caspase-independent inducers of cell death such as AIF (apoptosis-inducing factor), calpains, PARP are activated during that several caspase-independent inducers of cell death such as AIF (apoptosis-inducing factor), calpains, PARP are activated during retinal degeneration (Kaur et al., 2011; Paquet-Durand et al., 2010; Sanges et al., 2006). In our model caspase-3 activation seems to be involved in part of cell death in INL but neither in GCL nor ONL. However, co-localization of PAR accumulation with TUNEL-positive cells suggests that caspase-independent mechanisms are involved in cell death in ONL and GCL. It is important to highlight that although TUNEL is used as an apoptotic marker, it also can detect non-apoptotic DNA fragmentation, e.g. in necrosis (Grasl-Kraupp et al., 1995). Taken together, these findings suggest the involvement of multiple death signalling mechanisms (caspase-dependent and caspase-independent mechanisms) in retinal cell death after PDE6 inhibition in porcine retina.

We have described that PDE inhibition induced the inflammatory mediators TNF-alpha and IL-6 in porcine retina. Elevated levels of two of these inflammatory mediators have been recently described in the eye of patients with RP and rd10 mice (Yoshida et al., 2013a,b). TNF-alpha or IL-6 have been also observed in other eye diseases, including uveitis, proliferative vitreoretinopathy, retinal detachment and age-related macular degeneration (El-Ghrably et al., 1999; Klein et al., 2008; Nakazawa et al., 2011). TNF-α is likely secreted from activated macrophages, astrocytes, microglial cells and retinal Müller glial cells. It has been described that TNF-alpha has cytotoxic effects on photoreceptors (Nakazawa et al., 2006, 2011). TNF-alpha...
can trigger several well-characterized death-promoting (caspase-dependent and caspase-independent cell death) and survival-promoting pathways, depending upon the predominating signaling pathway in the particular cell type (Maianski et al., 2003). TNF-alpha binding to cell surface receptors such as TNF receptor 1 mediates activation of initiator caspases (caspase-8, caspase-10), and finally triggers cleavage of effector caspases (extrinsic pathway of cell death) (Nagata, 1997). TNF-alpha binding to cell surface receptors may also elicit anti-apoptotic responses mediated by the activation of the NF-kB pathway. Several evidence shows that TNF-alpha is also involved in the intrinsic pathway of cell death that is initiated by cellular and DNA damage and particularly employs mitochondria. TNF-alpha and other stimuli can reduce the mitochondrial transmembrane potential resulting in release of mitochondrial factors such as cytochrome c or AIF. AIF rapidly translocates from mitochondria to the nucleus and induces nuclear fragmentation and cell death by autophagic degeneration (Suo et al., 2010; Munemasa et al., 2010; Tezel and Yang, 2004; Lorenzo et al., 1999; Daugas et al., 2000). The translocation of AIF has been implicated in several types of neuronal death, including photoreceptor and ganglion cell death (Hisatomi et al., 2001; Mizukoshi et al., 2010; Thapa et al., 2012; Sanges et al., 2006). Inhibition of nuclear AIF translocation delays retinal degeneration of RCS rats, a model of retinitis pigmentosa (Murakami et al., 2008).

PARP-1 activation in response to excessive DNA damage triggers the release of AIF from mitochondria and promotes PARP-1-dependent cell death or parthanatos. AIF is a high-affinity PARP-1 activator and initiates a series of events that lead to nuclear fragmentation and cell death.

Fig. 6. PDE inhibition triggers oxidative stress and cytokine production cone-enriched cultures of porcine neuroretina. Control retinal explants or explants treated with Zaprinast (100 nmol/mL) were prepared as described in Materials and methods. (A) Effect of Zaprinast on nitric oxide formation (measurement of nitrates and nitrites (NOX)). Intracellular (iNOX) and extracellular nitrites and nitrates (eNOX) were measured by Griess reaction. (B) Effect of Zaprinast on the total antioxidant capacity and malonyldialdehyde formation (TBARS formation). (C) Effect of Zaprinast on TNF-alpha and IL-6 content. Each sample was measured in duplicate, and the values are the mean ± SEM of twelve cultures. Values significantly different from own control are indicated by asterisks "p < 0.05, **p < 0.01 (paired student t-test).
binding protein, PAR-binding by AIF is required for its release from the mitochondria, translocation to the nucleus, and cell death (Wang et al., 2011). PARP activation and PAR accumulation have been linked to mitochondrial death and AIF translocation to the nucleus in photoreceptor cell death in rd1 mice (Paquet-Durand et al., 2007).

The other inflammatory mediator upregulated in these cultures, IL-6 is a pleiotropic cytokine with a role in inflammation, angiogenesis, cell differentiation and neuronal survival. In the retina, IL-6 is synthesized by Müller cells and the RPE (Benson et al., 1992; Yoshida et al., 2001). A neuroprotective role for IL-6 has been suggested in different animal models of ocular injury, in vitro studies, retinal vein occlusion, diabetic macular oedema and experimental glaucoma (Chong et al., 2008; Funatsu et al., 2009; Noma et al., 2009) suggesting that IL-6 upregulation after injury may serve to control photoreceptor apoptosis (Chong et al., 2008).

Retinal degeneration induced by PDE inhibition was accompanied by oxidative stress in porcine retina. Retina is normally protected from oxidative damage by the presence of enzymes such as superoxide dismutase and catalase (De La Paz et al., 1996). Photoreceptors, which are the predominant cell type in the retina, are particularly susceptible to free radical damage or lipid peroxidation (Osborne and Wood, 2010), because retinal photoreceptor membranes have an unusually high concentration of docosahexanoic acid. Oxidative damage is a major factor contributing to cone cell death after the death of rods has occurred (Komeima et al., 2006; Shen et al., 2005). The increased levels of oxygen (hyperoxia), after death of rods result in progressive oxidative damage to cones in a transgenic pig model of RP and in multiple mouse models, including models of recessive and dominant RP. Antioxidant treatments can scavenger reactive oxygen species and promote cone survival and function (Komeima et al., 2006). In our study, we demonstrated the elevation of NO (NOX), which may increase peroxynitrite via the reaction the superoxide radical (Pryor and Squadrito, 1995). NO is an important regulator of homeostatic processes in the eye and its over-expression could contribute to pathological conditions in RP (Komeima et al., 2008).

We hypothesize that cGMP accumulation induces oxidative stress that probably induces microglial activation, as described in rd mice, that in turns upregulates TNF-alpha contributing to the cell death. TNF-alpha can activate different cell death pathways including caspase-3, and PARP. On the other hand, cGMP accumulation leads to calcium influx and calpain activation. We believe that PDE6 inhibition activates more than one apoptotic pathway (caspase-dependent and caspase-independent) as occurs in other experimental models of retinal degeneration (Gómez-Vicente et al., 2005; Kaur et al., 2011). Moreover, our findings suggest that different retinal cell types follow different apoptotic pathways.

In summary, PDE6 mutations induce retinal degeneration in small animal models (rd1, rd and rd10 mice), but eye size and anatomic differences suggest that should be useful to have alternative models for studying retinal rescue strategies or design new drugs intended for humans. Porcine eyes are closer in size to human eyes and have a rich supply of rod and cones. Our organotypic culture of porcine cone-enriched retina exposed to ZAPRINAST may provide a helpful model to design and assay some treatments thus replacing or reducing animal experiments.

However, this kind of culture has its own limitations. Organotypic cell culturing involves transfection of the optic nerve and mechanical retinal detachment causing photoreceptor loss and retrograde retinal ganglion cell degeneration. To minimize this problem, use of detached samples as controls is necessary. In the future, we aim at improving the viability of organotypic cell cultures, although it is difficult to culture retinal neurons for long periods perhaps due to the high energy requirements of the retina.
