Herein we report the synthesis of a tetrathiafulvalene (TTF)-based MOF, namely MUV-2, which shows a non-interpenetrated hierarchical crystal structure with mesoporous one-dimensional channels of ca. 3 nm and orthogonal microporous channels of ca. 1 nm. This highly stable MOF (aqueous solution with pH values ranging 2-11 and different organic solvents), possessing the well-known [Fe₂(µ₂-O)(COO)] secondary building unit, has proven to be an efficient catalyst for the aerobic oxidation of dibenzothiophenes.

Introduction

During the last two decades, the design and preparation of metal-organic frameworks (MOFs) 1–3 have attracted a big deal of attention due to their high potential in several applications such as gas storage and separation, 4 sensing, 5 and catalysis, 6 among others. In particular, the combination of both large pores and high stability is of high interest towards practical applications. However, most of reported MOFs are microporous (pore size < 2 nm) and there are only few examples of mesoporous MOFs (2-50 nm) combining both large pores size and high stability such as MIL-100, MIL-101 or PCN-600. 2–9 Recently, the preparation of microporous-mesoporous hierarchical MOFs has become a subject of great interest since micropores contribute to the bulk of the surface area whereas mesopores provide a better accessibility to larger molecules to quickly diffuse, becoming very attractive for catalytic applications. 10 During the last years, several strategies have been reported to construct hierarchical MOFs that usually require multi-step and lengthy synthetic procedures which also lack structural control of the mesopores. 11–14 In contrast, the direct formation of highly-stable and hierarchical MOFs presenting both micro- and mesopores in their crystalline structures (i.e. in an ordered manner) is limited, up to our knowledge, to the material NU-1000, which is based on the Zr₄(µ₃-OH)₄(OH)₉ cluster and 1,3,6,8-tetrakis(p-benzoic acid)pyrene ligand. 15 This material possess micro pores and mesopores that run parallel along the same axis direction. In catalysis, it has been found that the combination of micro- and mesopores in a hierarchical material increases notably its activity by favoring diffusion of substrates and reagents, particularly for bulky reagents. 16

On the other hand, tetrathiafulvalene (TTF) and its several derivatives are among the most versatile molecules which exhibit interesting redox properties, electron-donor character and potential application as molecular conductors. 17 The use of TTF as a ligand for the design of porous coordination polymers can give rise to multifunctional materials combining different physical properties. 18–20 For example, Dincă and coworkers have recently reported the use of the ligand tetrathiafulvalene tetrabenzoic acid (H₄TFTB) with various transition metals (II) obtaining a family of isomorphous and microporous TTF-based MOFs exhibiting tunable electrical conductivity. 21,22 More recently, the same ligand has also been used for the preparation of a TTF-based MOF with Mg(II) which exhibits permanent mesopores. 23

Herein, we report the synthesis, structure determination and physical properties of MUV-2 (MUV: Materials of University of Valencia), a highly stable TTF-based MOF with a unique non-interpenetrated hierarchical crystal structure with mesoporous channels disposed orthogonal to microporous channels. Moreover, the advantages of MUV-2 respect to widely used MOFs catalyst will be clearly demonstrated for a reaction of large applied interest, illustrating the advantages of having a hierarchical MOF with large mesopores and high stability.

Results and discussion

MUV-2 was prepared according to an adapted synthetic methodology 24 using the preformed cluster [Fe₂O(CH₃COO)]₄ClO₄ as starting material. Reaction of [Fe₂O(CH₃COO)]₄ClO₄, H₂TFTB, and acetic acid in N,N-dimethylformamide (DMF) at 90°C for 72 h yielded dark red needle single crystals of MUV-2 that were used to determine the crystal structure by single-crystal X-ray diffraction (XRD) (Scheme 1). The bulk material was exhaustively washed with large amount of DMF and immersed in the solvent overnight in order to remove any unreactive starting materials. Finally, the powder was immersed with EtOH at 65°C during 3 h, filtered and dried at room temperature. The infrared (IR) spectra of the

powder discarded the presence of unreactive starting material (Fig. S1).

Single-crystal X-ray diffraction data were collected up to 1 Å resolution at the I19 beamline facilities at Diamond Light Source (UK). MUV-2 crystallises in the space group P-62m and the unit cell parameters are \( a = b = 33.3 \) Å and \( c = 12.4 \) Å and consists of 6-connected \( \text{[Fe}_3(\mu_3-O)(\text{COO})_6] \) SBUs and tetratomic TTFTB\(^{6-}\) ligands. Considering each TTFTB ligand as a four-connected node and each \( \text{Fe}_3(\text{COO})_6 \) unit as a six-connected node, MUV-2 can be simplified as a 4,6-connected network with ttp topology (Fig. S2), an unusual topology previously observed in two lanthanoid-based MOFs.\(^{25,26}\) The non-interpenetrated crystal structure reveals large hexagonal mesoporous 1-D channels of ca. 3 nm along the c-axis which are formed by six TTF ligands and six clusters \( \text{[Fe}_3(\mu_3-O)(\text{COO})_6] \) (Fig 1a). TTF moieties are significantly twisted around the central C=C bond with dihedral angle of 20° whereas the planes formed by the two dithiole rings (planes S1-C1-C2-S2 and S3-C5-C6-S4) have a dihedral angle of 41° (Fig. S3). The torsion angles of S2-C3-S1-C1 and C1-C2-S2-C3 are 17° and 11°, respectively, which are typical for neutral TTFs. The phenyl rings exhibit a large distortion respect to the TTF core with dihedral angles of 62° with the latter. In contrast to NU-1000, where microporous channels are running parallel to the mesoporous ones,\(^{27}\) the crystal structure of MUV-2 shows that microporous channels of ca. 1 nm (9.5 x 12 Å) are disposed orthogonal to the mesoporous channels and are formed between two TTF ligands and two \( \text{[Fe}_3(\mu_3-O)(\text{COO})_6] \) clusters (Fig. 1b). In addition, microporous cages are constructed of three TTFTB ligands and two \( \text{[Fe}_3(\mu_3-O)(\text{COO})_6] \) SBUs (Fig. 1c) leading to a remarkable open structure with a calculated free volume of ca. 82 %. Note that the crystal structure of MUV-2 contains the precursor \( \text{[Fe}_3(\text{CH}_3\text{COO})_6]\text{ClO}_4 \) within the pores since it was determined from the as-synthesised material without the washing and activation procedure.

Mössbauer spectroscopy, magnetic measurements, solid-state cyclic voltammetry and Raman spectroscopy are consistent with the \( \text{[Fe}_3(\mu_3-O)(\text{COO})_6] \) cluster being formed by three \( S = 5/2 \) Fe(III) ions in octahedral environments, and the TTF ligands being neutral, thus yielding a material with formula \( \text{[TTFTB}_3(\text{Fe}_3\text{O}_2)\text{(H}_2\text{O})_4\text{(OH)}_3] \) which was in agreement with EDAX analysis of MUV-2 (see Figs. S4-S9). It is important to note that one of the three coordinated \( \text{H}_2\text{O} \) molecules in the cluster is present as negatively charged \( \text{OH}^- \) hydroxide in order to maintain the charge balance.

Thermogravimetric analysis (TGA) of washed MUV-2 exhibited a sharp mass loss of 20 % between 25 and 100 °C which corresponds to the elimination of solvent molecules (Fig. S10). TGA shows a large plateau above 200 °C until the final decomposition at 350 °C.
Activation of MUV-2 was performed by heating the washed material at 150 °C during 2 h. Its crystallinity was confirmed by powder X-ray diffraction (PXRD) observing that the principal peak is slightly shifted to 3.4° when heating (Fig. 2) and recovers the initial PXRD pattern upon resolvation (Fig. S11). Additionally, MUV-2 shows an extraordinary chemical stability in aqueous solutions with pH values ranging from 2-11 and in different organic solvents for 24 h. The PXRD patterns showed that crystallinity is maintained under these conditions (Fig. S12) and the CO₂ adsorption capacity is well preserved, for example, after treatment with pH = 2 and 11 aqueous solution (Fig. S20), with only a minor reduction.

The N₂ adsorption isotherm at 77 K revealed a combination of Types I and IV isotherms, resulting from the presence of micropores and mesopores, respectively. Thus, a steep N₂ adsorption occurs at low p/p₀ while a slight secondary uptake was also found due to the mesopore filling. It was observed a plateau in the N₂ uptake of 16 mmol/g (Fig. S13). MUV-2 has a BET surface area of 1220 m²/g which is higher than those for other reported mesoporous TTF-based MOFs. A micropore volume of 0.52 cm³/g was found using the Dubinin-Radushkevich equation and the pore size analysis by means of the Barrett-Joyner-Halenda (BJH) method revealed a pore size of 38.7 Å (Fig. S15). Fig. 3 shows the CO₂ and CH₄ isotherms at 298 K, revealing a high sorption capacity for both gases comparable to that of MIL-100.²⁷

The superior catalytic activity of MUV-2 due to the presence of mesopores with respect to widely used MIL MOFs as heterogeneous catalyst was clearly evidenced for the aerobic oxidation of dibenzothiophene (DBT) in long chain alkanes as solvent (Scheme 2). DBT is a model compound of reluctant aromatic sulphur compounds present in diesel. Legal regulations require diminishing the sulphur content in diesel down to the ppb scale. One of the possibilities is to perform oxidation of the fuels to convert the sulphur-containing organic compounds to the corresponding sulfones (generally soluble in water) that can be removed from the fuel by washing. It has recently been reported that DBT can be oxidized by molecular oxygen to the corresponding sulfone (DBTO₂) using MIL-101(Cr or Fe) as solid catalyst, although an induction period, probably related to diffusion problems, was observed.

![Tube](image.png)

**Scheme 2.** Aerobic oxidation of DBT to DBTO₂ using MUV-2 as catalyst.

Fig. 4 shows the time conversion plots for DBT disappearance and DBTO₂ formation in n-dodecane (plotted as sulphur content) comparing the temporal profile using MUV-2, MIL-101 (Fe) and MIL-100 (Fe), showing that MUV-2 is the best performing catalyst. Since all the three MOFs contained the same type of Fe₇μ₃O active centre, the higher catalytic activity of MUV-2 can be attributed to the more

---

**Fig. 2.** Powder X-ray diffraction patterns of simulated, as-synthesised and desolvated MUV-2.

**Fig. 3.** Gas adsorption isotherms of CO₂ (black) and CH₄ (red) on MUV-2 at 298 K (lines correspond to the best fits). Data at other temperatures are shown in the Supporting Information.

The isosteric heat of adsorption (qₑₗ) of CO₂ decreases from 30 to 20 kJ/mol, which remains constant in the case of CH₄ at around 16 kJ/mol within the studied loading range (Fig. S18). These values clearly indicate the highest affinity of MUV-2 for the CO₂, rather than for the CH₄. The isosteric heat of adsorption of CO₂ at zero coverage (qₑ₀) of MUV-2 is comparable to that of a LTA zeolite of Si/Al ratio of around 6, and that of MIL-101 and in the same range of a wide variety of MOFs.²⁹
favourable diffusion due to the presence of large pores in this material (see Table S3), as demonstrated with three different control experiments. To gain understanding on the origin of the induction period and its dependency on the pore size of MUV-2, this solid was contacted with n-dodecane containing DBT in the absence of O₂ for 2h, and then O₂ was introduced into the flask, whereby an immediate oxidation of DBT without induction period was observed (see Fig. S21a). A similar observation, i.e. a lack of induction period, was also noted when MUV-2 was boiled in n-dodecane containing O₂ and two hours later DBT was added (see Fig. S21b). Finally, no reduction of the induction period is observed if MUV-2 is heated in n-dodecane for two hours before introducing O₂ and DBT in the system (see Fig. S21c). This rationalisation is in agreement with the fact that, besides higher reaction rates, the induction period is remarkably shortened to about 1 h using MUV-2.

![Graphs showing sulfur content conversion plots](image)

**Fig. 4.** Aerobic oxidation of DBT (a,b) to DBTO₂ (c,d), plotted as sulfur content, using MUV-2 (■), MIL-101 (Fe) (●), MIL-100 (Fe) (▲) and in the absence of catalyst (♦) using ), n-dodecane (a, c) or diesel (b, d). Reaction conditions: catalyst: 0.012 mmol of Fe, DBT (1150 mg L⁻¹), solvent (10 mL), O₂ (1 atm), 140 °C.

From the application point of view, desulfuration of diesel should be carried out in the presence of a mixture of hydrocarbons from C13 to C18. Since diffusion is a limiting factor in this condition, the changes from model n-dodecane as solvent to real diesel was accompanied by a considerable decrease in activity in the case of MIL-101.14 It is of interest, therefore, to determine the performance of MUV-2 for aerobic oxidation in diesel as solvent. The results, presented in Fig. 4b, d, provide a comparison of the time-conversion plots for DBT oxidation using MIL-101(Fe), MIL-100(Fe) and MUV-2. As it is observed, the difference in catalytic activity in diesel as solvent remarkably favors MUV-2, showing the advantage of this MOF under these conditions. Reusability and productivity tests also show the high stability of MUV-2 as solid catalyst (Fig. S22 and S23), which is also active for different DBT derivatives (4-MeDBT and 4,6-Me₂DBT) (Fig. S24).

Hot-filtration tests were performed by filtering MUV-2 out from the hot reaction mixture after 2 h. At this point, the sulphur content was about 125 ppm (cf. the initial 200 mg L⁻¹), and the clear supernatant was allowed to continue the reaction in the absence of solid particle, observing a very minor progress of about 20 mg L⁻¹ sulphur content decrease in the subsequent 3 h (Fig. S25c). In contrast, a twin reaction in where MUV-2 was not filtered achieves a complete sulphur removal from initial 200 mg L⁻¹ in 5 h. These results indicate that, after initiation of the reaction, only a very minor contribution of leaching and homogeneous oxidation is occurring. In addition, control experiments using as homogeneous catalysts either chromium (III) acetate (0.6 mg of Cr), the preformed [Fe₂O(CH₂COO)₆]ClO₄ at the loadings corresponding to those present in MUV-2 or leached out during the reaction or H₂TTFTB showed in all cases negligible conversion, indicating that Cr or Fe transition metals at these concentrations or the ligand are not able to promote DBT oxidation (Fig. S25).

A combination of quenching experiments and spectroscopic studies has been used to address the reaction mechanism and, particularly, to determine that the primary reactive oxygen species responsible for oxidation is HOO⁻ (see Fig. S26 and S27). Thus, performing the oxidation in the presence of DMSO, a selective hydroxyl radical scavenger, does not influence much the time-conversion plot, while, in contrast, the presence of p-benzoquinone, a selective quencher of superoxide and hydroperoxy radicals, strongly inhibited DBT oxidation to DBTO₂. In addition, admission of oxygen into thermally dehydrated MUV-2 (220 °C, 5h) at 140 °C lead to the appearance of two new vibration bands in the Raman spectra at 1502 and 1161 cm⁻¹ that can be attributed to physisorbed and Fe-O-O, respectively (Fig. S27). This metal-peroxo could abstract a hydrogen atom from the medium (n-dodecane), generating hydroperoxy radicals that would initiate DBT oxidation. This hypothesis is supported by the observation of some very minor undetermined oxidation products from n-dodecane.

**Conclusions**

In summary, we have demonstrated that MUV-2, which possesses a hierarchical crystal structure with hexagonal mesoporous channels running orthogonal to the micropores, shows high thermal and chemical stability. This hierarchical structure is highly relevant for the catalytic activity of MUV-2 in the aerobic oxidation of DBT in long chain alkanes as solvents, whereby a dramatic increase in activity with respect to related MIL-100 and MIL-101 has been observed.

**Experimental**

**General methods and materials**

All reagents and solvents employed for the synthesises were of high purity grade and were purchased from Sigma-Aldrich Co., and TCI. ¹H NMR spectra were recorded using a Bruker DPX300 (300 MHz) spectrometer and Me₄Si as an internal standard. Infrared spectra
were recorded in a FT-IR Nicolet 5700 spectrometer in the 4000-400 cm⁻¹ range using powdered samples diluted in KBr pellets. Thermogravimetric analysis was carried out with a Mettler Toledo TGA/SDTA 851 apparatus in the 25-600 °C temperature range under a 10 °C/min scan rate and a N₂ flow of 30 mL·min⁻¹. Powder X-ray diffraction spectra were recorded using 0.7 mm borosilicate capillaries that were aligned on an Empyrean PANalytical powder diffractometer, using Cu Kα radiation (λ = 1.54056 Å).

**Synthesis of MUV-2**

Bulk: 20 mg of H₂TTFTB, 20 mg of [Fe₃O(CH₃COO)₆]ClO₄ and 0.8 ml of acetic acid were dissolved in 4 ml of DMF in a 10 ml Pyrex vial. The mixture was heated in an oven at 90 °C for 72 h. After cooling down to room temperature, dark brown powder was collected by filtration. The powder was washed with large amount of DMF in order to remove the unreacted ligand and [Fe₃O(CH₃COO)₆]ClO₄ and immersed in DMF during one night. Finally, the product was immersed in EtOH during 3 h at 65 °C, washed and collected by filtration (19.6 mg; 80 %).

**Crystal data for MUV-2**

X-ray data was collected at 100 K on red needles using a synchrotron radiation at single crystal X-ray diffraction beamline I19 in Diamond Light Source, equipped with a Pilatus 2M detector and an Oxford Cryosystems nitrogen flow gas system. Despite of using synchrotron radiation, crystals of MUV-2 only diffracted to 1.2 Å of resolution. Refinement details can be found in the Supporting Material. Space group P-62m, a = b = 33.298(3) Å, c = 12.3958(7) Å, V = 11903(2) Å³, R₁ (F) = 0.0324, wR² (F²) = 0.0929.

**Gas sorption**

High-pressure adsorption isotherms of CO₂, CH₄ and N₂ were measured at different temperatures ranging from 283 to 333 K in an IGA-3 gravimetric analyser (Hiden Isochema) using approximately 50 mg of sample placed in the balance. Before each adsorption experiment, the sample was outgassed at 423 K under a final pressure of 10⁻⁵ Pa for four hours. The sample was then cooled down under high vacuum up to the target temperature that was controlled using a recirculating thermostatic bath. Adsorption measurements were performed by introducing the gas to build up the desired pressures of the isotherms. The heat of adsorption was calculated according to the Clausius–Clapeyron equation from the isotherms measured at different temperatures.

**Magnetic measurements**

Magnetic susceptibility measurements were carried out on single-phased polycrystalline samples with a Quantum Design MPMS-XL-5 SQUID susceptometer. The susceptibility data were all collected at 1 K min⁻¹, in the range 2-300 K with and applied field of 0.1 T. The susceptibility data were corrected from the diamagnetic contributions as deduced by using Pascal’s constant tables.

**Mössbauer**

Mössbauer spectra were collected in the temperature range 295–4 K in transmission mode using a conventional constant-acceleration spectrometer and a 25 mCi $^{57}$Co source in a Rh matrix. The velocity scale was calibrated using α-Fe foil. Isomer shifts, IS, are given relative to this standard at room temperature. The absorber was obtained by packing the powdered samples into a Perspex holder. The absorber thickness was calculated on the basis of the corresponding electronic mass-absorption coefficients for the 14.4 keV radiation. The low temperature spectra were collected in a bath cryostat with the sample immersed in liquid He at 4 K or in He exchange gas at 50 K. The spectra were fitted to Lorentzian lines using a non-linear least-squares method.

**Electrochemical measurements**

The electrochemical experiments were performed using an Autolab electrochemical workstation (Autolab-128N potentiostat/galvanostat) connected to a personal computer that uses Nova 2.1 electrochemical software. The powdered materials were mixed with Polytetrafluoroethylene (PTFE) in a mass ratio of 90:10 in ethanol and deposited on a 3 mm glassy carbon disc working electrode (which was polished sequentially with 0.3, 0.1 and 0.05 μm alumina powders and washed with deionised water before each experiment). A typical three-electrode experimental cell equipped with a platinum wire as the counter electrode, and a silver wire as the pseudoreference electrode was used for the electrochemical characterization of the working electrodes. All measurements were carried out with magnetic agitation and nitrogen bubbling. The electrochemical properties were studied measuring the CV at different scan rates in 0.1 M TBAPF₆/CH₃CN solution. Ferrocene was added as an internal standard upon completion of each experiment. All potentials are reported in V versus Ag/AgCl.

**Catalytic experiments**

5 mg of catalyst was placed on a round-bottom flask (25 mL). Activation of the MUV-2 catalyst was carried out by heating at 150 °C under vacuum overnight. Subsequently, the reaction temperature was fixed at 140 °C and the required reaction atmosphere was obtained by purging the system with a balloon containing O₂ under atmospheric pressure. The reaction time started by addition of a solution of DBT (200 mg L⁻¹ of S) in 10 mL of the reaction solvent to the preheated round-bottom flask. As reaction solvent, n-dodecane or commercial diesel (Repsol) were used. The mixture was continuously stirred magnetically at 500 rpm. The course of the reaction was followed by sampling 250 μl of the reaction mixture that was diluted with 250 μl of anisole and injected in a GC having a FI detector and a 30 m capillary column of 5% crosslinked phenyl methyl silicone. At the end of the reaction, the mixture was filtered to remove the solid while still hot and the organic phase was washed with three aliquots of 20 ml of water to remove the DBTO₂ product.
formed in the process. Selective radical quenching experiments using p-benzoquinone or DMSO were carried out as described above but with the addition of 20 mol% of these reagents with respect to the initial DBT at 1.5 h of the reaction time.
